Optimal energy conserving local discontinuous Galerkin methods for second-order wave equation in heterogeneous media

Ching-Shan Chou\textsuperscript{1}, Chi-Wang Shu\textsuperscript{2} and Yulong Xing\textsuperscript{3}

Abstract

Solving wave propagation problems within heterogeneous media has been of great interest and has a wide range of applications in physics and engineering. The design of numerical methods for such general wave propagation problems is challenging because the energy conserving property has to be incorporated in the numerical algorithms in order to minimize the phase or shape errors after long time integration. In this paper, we focus on multi-dimensional wave problems and consider linear second-order wave equation in heterogeneous media. We develop and analyze an LDG method, in which numerical fluxes are carefully designed to maintain the energy preserving property and accuracy. Compatible high order energy conserving time integrators are also proposed. The optimal error estimates and the energy conserving property are proved for the semi-discrete methods. Our numerical experiments demonstrate optimal rates of convergence, and show that the errors of the numerical solution do not grow significantly in time due to the energy conserving property.

Keywords: wave propagation, local discontinuous Galerkin method, energy conservation, optimal error estimate, heterogeneous media

1 Introduction

Wave propagation is a fundamental form of energy transmission, which arises in many fields of science, engineering and industry, and it is significant to geoscience, petroleum engineering, telecommunication, and the defense industry (see [19, 25] and the references therein). Efficient and accurate numerical methods to solve wave propagation problems are of fundamental importance to these applications. Experience reveals that energy conserving numerical methods, which conserve the discrete approximation of energy, are favorable because they are able to maintain the phase and shape of the waves accurately, especially for long time simulation. In [34], we have designed a high order accurate energy conserving local discontinuous Galerkin (LDG) method for the one-dimensional second-order wave equation with constant coefficient. In this paper, we focus on multi-dimensional problems in heterogeneous media, and develop optimally convergent LDG methods which also conserve the energy in the discrete sense.

The wave equation can be written in a second-order form, or an equivalent first-order hyperbolic system. Directly solving the second-order equation usually involves fewer unknown variables, therefore the resulting numerical schemes are more efficient. This saving can be significant in the three-dimensional applications. For the linear elasticity equations in three dimensions, three variables are used in the second-order form, while first-order system needs at least nine components [4]. In addition, there are many applications where the second-order PDEs appear naturally. When converted into first-order systems, they may admit a wider class of solutions, therefore some constraints are needed to ensure these solutions are solutions of the original second-order equation. This also increases difficulty to the design of numerical methods. Finally, it was also shown [2] that second-order equation may allow larger time step size, compared to the first-order system.

A vast amount of literature can be found on the numerical approximations of the second-order wave equation. The most common numerical method for solving the wave equation is to use the second order accurate centered finite difference operator. Finite difference
method provides an efficient solver, but it is usually limited by the geometry of the domain. The finite element method can handle complex geometry, but often dissipates energy. Here, we will confine our attention in finite element methods, in particular, discontinuous Galerkin (DG) methods. The DG methods belong to a class of finite element methods using discontinuous piecewise polynomial spaces for both the numerical solution and the test functions. They were originally devised to solve hyperbolic conservation laws with only first order spatial derivatives, e.g. [10, 11, 12, 14, 15]. They allow arbitrarily unstructured meshes, and have compact stencils. Moreover, they easily accommodate arbitrary $h$-$p$ adaptivity. The DG methods were later generalized to the LDG methods by Cockburn and Shu to solve convection-diffusion equations [13], motivated by successful numerical experiments from Bassi and Rebay [5] for the compressible Navier-Stokes equations.

Many DG methods have been developed for the wave equation in both first-order and second-order forms [12, 23, 20, 28, 31, 30, 1, 3], and some of these methods are also energy-conserving [21, 22, 8]. Usually, two approaches are commonly used to achieve the energy-conserving property. The first one is to introduce two staggered mesh sets, and define one set of solution on each mesh. This usually leads to higher computational cost, and moreover staggered mesh may be difficult to construct, especially for high dimensional complex domain and in the neighborhood of the boundary. Recently, Chung and Engquist [8, 9] have proposed an optimal, energy conserving DG method for the first-order wave equation using staggered grids. They introduced different meshes for different computational variables, and are able to prove the optimal convergence for unstructured meshes. The other approach to obtain energy-conserving method is to use the central numerical flux [21], i.e. the numerical flux along cell boundaries is evaluated by taking the average of two values of the numerical solutions from the two neighboring cells. However, only suboptimal convergence can be proven theoretically, and numerically, one can observe optimal convergence if even order polynomial space is used, and suboptimal if odd order polynomial space is used.

Usually it is difficult to obtain DG schemes for wave equations which are non-dissipative
(energy conserving for the physical energy) and optimal high order accurate. In [34], we have designed an energy conserving LDG method for the simple one dimensional second-order constant coefficient wave equation. We have proved that the proposed method has the optimal convergence rates in both the energy and $L^2$ norms, and the upper bound of the errors grows in time only in a linear fashion. In this paper, we consider the multi-dimensional wave problems in heterogeneous media. Extension of the previous work to the multi-dimensional problems on Cartesian meshes is discussed. Extra attention needs to be paid at the interface of different media to ensure the stability and energy conservation. Theoretical proof, as well as the numerical evidence, indicates that a good choice of the projection of the initial condition into the polynomial space is important to achieve optimal convergence rate. The semi-discrete LDG method will be coupled with high order explicit energy conserving time discretization. We remark here that since our scheme is non-dissipative, it is more oscillatory than the commonly used upwind (energy-dissipative) DG method when applied to problems with discontinuities. The advantage of energy-conserving methods is to solve smooth wave problems, with the attempt to resolve all waves for long time periods.

The outline of our paper is as follows. In Section 2, we present the semi-discrete LDG method, and prove its energy conserving property. The optimal error estimates, both in the energy norm and the $L^2$ norm, are analyzed in Section 3, and therein, the upper bound of errors is proved to grow linearly in time. The fully discrete LDG method, with the high order energy conserving time discretization, and its energy conserving properties are presented in Section 4. Section 5 contains numerical experiments that demonstrate the optimal convergence rates and energy conservation of the proposed LDG method. Finally, we give the concluding remarks in Section 6.
2 Local discontinuous Galerkin discretization

2.1 Model problem

In this paper, we primarily consider the second-order wave equation, on a bounded domain $\Omega$ in $\mathbb{R}^2$ or $\mathbb{R}^3$,

$$u_{tt} = \nabla \cdot (c(x) \nabla u), \quad x \in \Omega, \quad t \in [0,T], \quad (2.1)$$

where $c(x) \geq 0$, and this problem is subject to the initial conditions

$$u(x,0) = u_0(x), \quad u_t(x,0) = v_0(x). \quad (2.2)$$

The speed of wave propagation is the square root of $c(x)$, and it is denoted by $a(x)$, which is assumed to be piecewise smooth. Both homogeneous Dirichlet boundary conditions and periodic boundary conditions will be considered. We remark here that the results in the following sections will remain the same if a source term $f(x,t)$ is added to the equation (2.1), so for simplicity, we only consider (2.1) throughout this paper.

2.2 Notations

We consider a two-dimensional rectangular domain $\Omega$ for simplicity (extension to three dimension is straightforward), and without loss of generality, we denote it by $[0,L_x] \times [0,L_y]$. We discretize the computational domain $\Omega$ into rectangular cells $K_{i,j} = I_i \times J_j$, where $I_i = [x_{i-\frac{1}{2}},x_{i+\frac{1}{2}}]$, $i = 1, \cdots, N_x$ and $J_j = [y_{j-\frac{1}{2}},y_{j+\frac{1}{2}}]$, $j = 1, \cdots, N_y$. The center of each cell is $(x_i, y_j) = \left(\frac{1}{2}(x_{i-\frac{1}{2}} + x_{i+\frac{1}{2}}), \frac{1}{2}(y_{j-\frac{1}{2}} + y_{j+\frac{1}{2}})\right)$, and the mesh sizes are denoted by $h_i^x = x_{i+\frac{1}{2}} - x_{i-\frac{1}{2}}$ and $h_j^y = y_{j+\frac{1}{2}} - y_{j-\frac{1}{2}}$, with $h_x^x = \max_{1 \leq i \leq N_x} h_i^x$, $h_y^y = \max_{1 \leq j \leq N_y} h_j^y$, and $h = \max(h_x, h_y)$ the maximal mesh size. Regular meshes are used, namely, the ratio between the maximal and the minimal mesh sizes remains bounded during mesh refinement.
Let $\mathcal{T}_h$ be the family of partitions of $\Omega$ parameterized by $h > 0$, and we define
\[
\mathcal{E}_h^I := \text{set of all interior edges/faces of } \mathcal{T}_h,
\]
\[
\mathcal{E}_h^B := \text{set of all boundary edges/faces of } \mathcal{T}_h \text{ on } \Gamma = \partial \Omega,
\]
\[
\mathcal{E}_h := \mathcal{E}_h^I \cup \mathcal{E}_h^B.
\]

The piecewise polynomial space $V_h^k$ is defined as the space of tensor product piecewise polynomials of degree at most $k$ in each variable on every element $K_{i,j}$, that is,
\[
V_h^k = \{ v : v|_K \in Q^k(K), \forall K \in \mathcal{T}_h \},
\]
where $Q^k$ is the space of tensor products of one-dimensional polynomials of degree up to $k$. Note that functions in $V_h^k$ are allowed to have discontinuities across element interfaces. We extend this definition for vector-valued functions by defining
\[
\Sigma_h^k = \{ \mathbf{w} = (w_1, w_2)^T : w_l|_K \in Q^k(K), l = 1, 2, \forall K \in \mathcal{T}_h \}.
\]

The solution of the numerical scheme is denoted by $u_h$, which belongs to the finite element space $V_h^k$. We denote by $u_h(x_{i+1/2}, y)$ and $u_h(x_{i+1/2}, y)$ the limit values of $u_h$ at $x_{i+1/2}$ from the right cell $I_i \times J_j$ and from the left cell $I_i \times J_j$, respectively; $u_h(x, y_{j+1/2})$ and $u_h(x, y_{j+1/2})$ are defined similarly. The $L^2$ norm over the domain $\Omega$ is denoted by $\| \cdot \|$.  

2.3 The LDG method

In this subsection, we define the semi-discrete LDG method for the wave equation (2.1), by discretizing the space with the LDG method and leaving the time dependence continuous. The wave equation is written into a first order system by substituting the first order derivatives $u_x, u_y$ with the auxiliary variable $\mathbf{q} = (q^1, q^2)$:
\[
\begin{align*}
u_{tt} & = \nabla \cdot (a(x)\mathbf{q}), \\
\mathbf{q} & = a(x)\nabla u.
\end{align*}
\]
The LDG method for (2.5) is then formulated as follows: find $u_h, q_h^1, q_h^2 \in V^k_h$, such that

$$\int_{K_{i,j}} (u_h)_{tt} \psi dx + \int_{K_{i,j}} aq_h^1 \psi_x dx - \int_{J_j} \tilde{aq}_h^1 \psi(x_{i+\frac{1}{2}}^{-} - x_i^{-}, y) dy + \int_{J_j} \tilde{aq}_h^1 \psi(x_{i+\frac{1}{2}}^{+} - x_i^{+}, y) dy$$

$$+ \int_{K_{i,j}} aq_h^2 \psi_y dx - \int_{I_i} \tilde{aq}_h^2 \psi(x, y_{j+\frac{1}{2}}^{-}) dx + \int_{I_i} \tilde{aq}_h^2 \psi(x, y_{j+\frac{1}{2}}^{+}) dx = 0,$$

$$\int_{K_{i,j}} q_h^1 \phi dx + \int_{K_{i,j}} au_h \phi_x dx - \int_{J_j} \tilde{au}_h \phi(x_{i+\frac{1}{2}}^{-} - x_i^{-}, y) dy + \int_{J_j} \tilde{au}_h \phi(x_{i+\frac{1}{2}}^{+} - x_i^{+}, y) dy = - \int_{K_{i,j}} a_x u_h \phi dx,$$

$$\int_{K_{i,j}} q_h^2 \phi dx + \int_{K_{i,j}} au_h \phi_y dx - \int_{I_i} \tilde{au}_h \phi(x, y_{j+\frac{1}{2}}^{-}) dx + \int_{I_i} \tilde{au}_h \phi(x, y_{j+\frac{1}{2}}^{+}) dx = - \int_{K_{i,j}} a_y u_h \phi dx,$$

for all test functions $\psi, \phi, \varphi \in V^k_h$. The hatted terms, $\tilde{aq}_h^1$ and $\tilde{au}_h$, and the tilde terms, $\tilde{aq}_h^2$ and $\tilde{au}_h$, in (2.6)-(2.8) are the cell boundary terms obtained from integration by parts, and they are the so-called numerical fluxes. These numerical fluxes are single-valued functions defined on the cell boundaries, and they are essential to ensure numerical stability and capture certain properties of the PDEs, such as energy conservation in wave equations.

If the function $a(x)$ is continuous, the numerical fluxes can be determined following the one dimensional approach in [34]. For the hatted terms, we use the simple alternating fluxes,

$$\tilde{aq}_h^1 = \tilde{aq}_h^{1+}, \quad \tilde{au}_h = \tilde{au}_h^+, \quad (2.9)$$

where all quantities are computed at the same points $(x_{i+1/2}, y)$ (i.e., the cell interface). We remark that the choice of the fluxes (2.9) is not unique. We can, for example, alternatively choose the numerical fluxes to be

$$\tilde{aq}_h^1 = \tilde{aq}_h^{1-}, \quad \tilde{au}_h = \tilde{au}_h^- . \quad (2.10)$$

Similarly, one can use the numerical fluxes

$$\tilde{aq}_h^2 = \tilde{aq}_h^{2-}, \quad \tilde{au}_h = \tilde{au}_h^+ , \quad (2.11)$$

or

$$\tilde{aq}_h^1 = \tilde{aq}_h^{2+}, \quad \tilde{au}_h = \tilde{au}_h^- . \quad (2.12)$$

7
where all quantities are computed at the same points \((x, y_{j+\frac{1}{2}})\) (i.e., the cell interface).

However, if the function \(a(x)\) is discontinuous, the above numerical fluxes are not sufficient to render the correct accuracy and energy preserving property. Here we assume that \(a(x)\) is piecewise smooth and the discontinuities only occurs in the direction aligned with our spatial discretization, namely, either vertical or horizontal (or both). Thus, we can align the jumps of \(a(x)\) with cell interfaces. Theoretically, the natural interface condition (see [6]) for the two media is the continuity in \(u\) and the flux \(aq\), that is, \(u^- = u^+\) and \(a^-q^- = a^+q^+\). This continuity condition, however, is not consistent with the fluxes of the original LDG methods (2.7)-(2.8). Therefore, we propose to update the discretization of Eqs. (2.7) and (2.8) by:

\[
\int_{K_{i,j}} q_1^h \phi dx + \int_{K_{i,j}} u_h a\phi_x dx - \int_{J_j} \widehat{u}_h a\phi(x_{i+\frac{1}{2}}, y) dy + \int_{J_j} \widehat{u}_h a\phi(x_{i-\frac{1}{2}}, y) dy = -\int_{K_{i,j}} a x u_h \phi dx, \tag{2.13}
\]

\[
\int_{K_{i,j}} q_2^h \phi dx + \int_{K_{i,j}} u_h a\phi_y dx - \int_{L_i} \widehat{u}_h a\phi(x, y_{j+\frac{1}{2}}) dx + \int_{L_i} \widehat{u}_h a\phi(x, y_{j-\frac{1}{2}}) dx = -\int_{K_{i,j}} a y u_h \phi dx, \tag{2.14}
\]

for all test functions \(\psi, \phi, \varphi \in V^k_h\). Note that \(a\) is no longer included in the numerical flux. We will show later that this choice of discretization will provide correct accuracy and energy conservation property. For the hatted terms, we use the simple alternating fluxes,

\[
\widehat{a q}_h^1 = a^- q_1^{1-}, \quad \widehat{u}_h = u^+_h, \tag{2.15}
\]

or

\[
\widehat{a q}_h^1 = a^+ q_1^{1+}, \quad \widehat{u}_h = u^-_h, \tag{2.16}
\]

where all quantities are computed at the same points \((x_{i+\frac{1}{2}}, y)\) (i.e., the cell interface).

Similarly, one can use the numerical fluxes

\[
\widehat{a q}_h^2 = a^- q_2^{2-}, \quad \widehat{u}_h = u^+_h, \tag{2.17}
\]

or

\[
\widehat{a q}_h^2 = a^+ q_2^{2+}, \quad \widehat{u}_h = u^-_h, \tag{2.18}
\]

8
where all quantities are computed at the same points \((x, y_{j+\frac{1}{2}})\) (i.e., the cell interface).

If the numerical fluxes (2.16) and (2.18) are used, and if we denote \(K_{i,j}\) by \(K\) for simple presentation, the LDG methods can be equivalently reformulated as

\[
((u_h)_{tt}, \psi)_K + (aq_h, \nabla \psi)_K - (a^+ q_h^+ \cdot \nu, \psi)_{\partial K} = 0, \tag{2.19}
\]

\[
(q_h, \phi)_K + (au_h, \nabla \cdot \phi)_K - (u_h^-, a\phi \cdot \nu)_{\partial K} = -(u_h \nabla a, \phi)_K. \tag{2.20}
\]

where \((\cdot)_K\) denotes the \(L^2\) inner product, that is, \((f, g)_K = \int_K f \cdot g \, dx\).

2.4 Energy conservation

As is well-known, the important physical quantity, the energy \(E = \int_I (u_t^2 + u_x^2 + u_y^2) \, dx\), is conserved, in the linear wave equation (2.1). This property is often taken into consideration in the design of numerical schemes because experiences show that schemes conserving the discrete analogs of energy appears to approximate the solution better, especially in the long time behavior. In this subsection, we will show that the proposed semi-discrete LDG method conserves energy.

**Proposition 2.1.** The (continuous) energy

\[E_h(t) = \int_I \left( (u_h)_t^2 + (q_h^1)^2 + (q_h^2)^2 \right) \, dx \tag{2.21}\]

is conserved by the the semi-discrete LDG method (2.19)-(2.20) for all time.

**Proof.** By taking the time derivative of Eq. (2.20), and choosing the test function \(\phi = q_h\), one obtains

\[
((q_h)_t, q_h)_K + (a(u_h)_t, \nabla \cdot q_h)_K - ((u_h^-)_t, aq_h \cdot \nu)_{\partial K} = -(u_t \nabla a, q_h)_K. \tag{2.22}
\]

In Eq. (2.19), we choose the test function to be \((u_h)_t\):

\[
((u_h)_{tt}, (u_h)_t)_K + (aq_h, \nabla (u_h)_t)_K - (a^+ q_h^+ \cdot \nu, (u_h)_t)_{\partial K} = 0. \tag{2.23}
\]
Addition of Eq. (2.22) and Eq. (2.23) becomes
\[
\sum_{K \in T_h}(u^t_h, a q^t_h - ((u^t_h)_t, a q^t_h)_{\partial K} - (a q^t_h + q^t_h \cdot \nu, (u^t_h)_t)_{\partial K} = 0,
\]
and with integration by parts, we obtain
\[
\sum_{K \in T_h}(u^t_h, a q^t_h)_{\partial K} - ((u^t_h)_t, a q^t_h)_{\partial K} - (a q^t_h + q^t_h \cdot \nu, (u^t_h)_t)_{\partial K} = 0.
\]

(2.24)

By summing up Eq. (2.24) over all cells and using the periodic or Dirichlet boundary conditions, we have
\[
0 = \sum_{K \in T_h}(u^t_h, a q^t_h)_{\partial K} - ((u^t_h)_t, a q^t_h)_{\partial K} - (a q^t_h + q^t_h \cdot \nu, (u^t_h)_t)_{\partial K} = 0.
\]

Therefore the quantity \( E_h \) is invariant in time.

\[\square\]

3 Error estimate

In this section, we derive the optimal error estimates for the energy conserving LDG method (2.19)-(2.20) proposed in Section 2. The error estimate in the energy norm will be presented first, and then the analysis will be extended to the \( L^2 \) norm. We will also show that these error bounds are both linear in time.

3.1 Projections and inequalities

First, we introduce the projections and other notations that will be used throughout this paper. We use \( P \) to denote a weighted \( L^2 \) projection of a function \( \omega(x) \) with \( k + 1 \) continuous derivatives into space \( V^k_h \), that is:
\[
(P \omega, a \phi)_{\Omega} = (\omega, a \phi)_{\Omega},
\]
for any \( \phi \in Q^k \) on \( K \).
In addition, a one-dimensional projection $P_x^-$ for a real-valued function $\omega$, which projects $\omega$ into the one-dimensional piecewise polynomial space of degree $k$ while taking the values of $\omega$ at the cell interface, is defined as follows

\[(P_x^- \omega, a\phi)_{I_i} = (\omega, a\phi)_{I_i}, \forall \phi \in P^{k-1}(I_i) \quad \text{and} \quad (P_x^- \omega)(x_{i+\frac{1}{2}}) = \omega(x_{i+\frac{1}{2}}). \quad (3.1)\]

Similarly, the one-dimensional projection $P_x^+ \omega$ is defined as the projection of $\omega$ such that

\[(P_x^+ \omega, a\phi)_{I_i} = (\omega, a\phi)_{I_i}, \forall \phi \in P^{k-1}(I_i) \quad \text{and} \quad (P_x^+ \omega)(x_{i-\frac{1}{2}}) = \omega^+(x_{i-\frac{1}{2}}),\]

and the one-dimensional projection on the $y$-direction $P_y^\pm$ are defined in the same way. Since the Cartesian meshes are used in this paper, we can extend the definition of the above $P_x^\pm$ to two dimension: on a two-dimensional rectangle element $K_{i,j} = I_i \times J_j$, the projection $P^-$ for scalar functions are defined as

\[P^- = P_x^- \otimes P_y^- . \quad (3.2)\]

This projection $P^-$ on the Cartesian meshes has been shown in [18, Lemma 3.7] to have the following super convergence property: for $\eta \in H^{k+2}(\Omega), \rho \in \Sigma_h^k$,

\[|(\eta - P^- \eta, a\nabla \cdot \rho)_{T_h} - (\eta - \hat{P^-} \eta, a\rho \cdot \nu)_{E_h}| \leq Ch^{k+1} \|\eta\|_{H^{k+2}(\Omega)} \|\rho\|_{\Omega}, \quad (3.3)\]

where the “hat” term denotes the numerical flux.

Another projection $\Pi^+$, for vector-valued functions $\rho = (\rho_1, \rho_2)$, is defined as

\[\Pi^+ \rho = (P_x^+ \otimes P_y \rho_1, P_x \otimes P_y^+ \rho_2), \quad (3.4)\]

where $P_x$ and $P_y$ are the one-dimensional $L^2$ projections in the $x$ and $y$ directions, respectively. One can easily observe that, for any $\rho \in [H^1(\Omega)]^2$, the restriction of $\Pi^+ \rho$ to $I \otimes J$ ($= K_{i,j}$) are elements of $[Q^k(I \otimes J)]^2$ that satisfy

\[(\Pi^+ \rho - \rho, a\nabla w)_{I \otimes J} = 0, \quad (3.5)\]
for any $w \in Q^k(I \otimes J)$, and

\[
\begin{align*}
\left( (\Pi^+ \mathbf{\rho}(x_{i-\frac{1}{2}}, \cdot) - \mathbf{\rho}(x_{i-\frac{1}{2}}, \cdot)) \cdot \mathbf{\nu}, aw(x_{i-\frac{1}{2}}, \cdot) \right)_J & = 0, \quad \forall w \in Q^k(I \otimes J), \\
\left( (\Pi^+ \mathbf{\rho}(\cdot, y_{j-\frac{1}{2}}) - \mathbf{\rho}(\cdot, y_{j-\frac{1}{2}})) \cdot \mathbf{\nu}, aw(\cdot, y_{j-\frac{1}{2}}) \right)_I & = 0, \quad \forall w \in Q^k(I \otimes J),
\end{align*}
\]

(3.6)

(3.7)

where $\mathbf{\nu}$ is the outward normal vector of the integrated domain. These projections defined above have the following approximation property (see [18, 35]): for any $\eta \in H^{k+1}(\Omega)$ and $\mathbf{\rho} \in [H^{k+1}(\Omega)]^2$,

\[
\| P^\pm \eta - \eta \|_\Omega \leq C h^{k+1} \| \eta \|_{H^{k+1}(\Omega)}, \quad \| \Pi^\pm \mathbf{\rho} - \mathbf{\rho} \|_\Omega \leq C h^{k+1} \| \mathbf{\rho} \|_{H^{k+1}(\Omega)},
\]

(3.8)

where $C$ is independent of the mesh size $h$.

Finally, we denote the errors by

\[
\begin{align*}
e_u & = u - u_h = \eta_u + \zeta_u, \quad \eta_u = u - P^- u, \quad \zeta_u = P^- u - u_h, \\
e_q & = q - q_h = \eta_q + \zeta_q, \quad \eta_q = q - \Pi^+ q, \quad \zeta_q = \Pi^+ q - q_h,
\end{align*}
\]

(3.9)

which, from left to right, respectively represent the errors between the exact solution and the numerical solution, the projection errors, and the errors between the numerical solution and the particular projection of the exact solution. Note that the signs of the projection $P^\pm_h$ and $\Pi^\pm$ of $u$ and $q$ in (3.9) are consistent with the choice of the numerical fluxes in (2.9). So if the other set of numerical fluxes are chosen, the signs of $P^\pm_h$ and $\Pi^\pm$ in (3.9) should be changed accordingly.

### 3.2 Error estimate in the energy norm

The optimal error estimates of the proposed LDG method rely upon carefully chosen projections of the initial conditions. Note that we have two initial conditions in (2.2), one for $u$ and the other for $u_t$. We take the initial condition $u_h(x, 0)$ as $P^-_h u(x, 0) = P^-_h u_0(x)$, which is consistent with the choice of the numerical fluxes (2.9). The other initial condition $(u_h)_t(x, 0)$ is given by the standard $L^2$ projection. Thus, we have the following lemma.
Lemma 3.1. Suppose the initial conditions of the LDG scheme (2.6)-(2.7) are given by

\[ u_h(x,0) = P_h^{-1} u(x,0), \quad (u_h)_t(x,0) = P_h u_t(x,0), \] (3.10)

there holds the following error estimate

\[ \|\zeta_u(0)\| = 0, \quad \|\zeta_q(0)\| \leq C h^{k+1}, \quad \|(\zeta_u)_t(0)\| \leq C h^{k+1}, \] (3.11)

and

\[ ((e_u)_t(0), v)_\Omega = 0, \quad \text{for any } v \in Q^k. \] (3.12)

The proof of this Lemma is similar as that in [34], and is therefore omitted here.

Remark 3.1. We would like to emphasize that this special choice of initial condition is critical in the optimal convergence rate of the proposed LDG method. The optimal error estimate shown below is based on these initial conditions, and this is confirmed by our numerical experiments. As shown in Section 5, if the standard \( L^2 \) projections are used for both \( u \) and \( u_t \), the convergence rate becomes oscillating and does not converge to the desired \( k+1 \) accuracy. Although previous studies on LDG methods showed that the different choices of initial condition have little impact on the convergence/superconvergence results [7, 27, 24], different initial condition does make a difference for our method. We believe it is related to the fact that current energy conserving method has no numerical dissipation, and therefore it is more sensitive to the error in the initial conditions. So it is critical to choose an “optimal” initial condition such that the resulting energy-conserving method is optimal.

Based on initial conditions (3.10), we have the following error estimate in the energy norm.

Proposition 3.1. Let \( u \) and \( q \) be the exact solutions of the wave equation (2.5), and \( u_h, q_h \) be the numerical solutions of the semi-discrete LDG method (2.19)-(2.20) with the initial conditions (3.10), there holds the following error estimates:

\[ \|(e_u)_t\| \leq C h^{k+1}(t + 1), \quad \|e_q\| \leq C h^{k+1}(t + 1), \] (3.13)
where the constant $C$ depends on $|\nabla a|_\infty$, $\|u\|_{k+3}$ and $\|u_t\|_{k+2}$.

**Proof.** The error equations of the proposed LDG method are

\[
((e_u)_{tt}, \psi)_K + (ae_q, \nabla \psi)_K - (a^+ e_q^+ \cdot \mathbf{v}, \psi)_{\partial K} = 0, \quad (3.14)
\]

\[
(e_q, \phi)_K + (ae_u, \nabla \cdot \phi)_K - (e_u^-, a \phi \cdot \mathbf{v})_{\partial K} = -(e_u \nabla a, \phi)_K, \quad (3.15)
\]

for all test functions $\psi \in V_h^k$ and $\phi \in \Sigma_h^k$, which can be derived by subtracting (2.19)-(2.20) from the weak formulation satisfied by the exact solutions $u$ and $q$.

Using the properties of the projections $P^-$ and $\Pi^+$, the error equations become

\[
((\zeta_u)_{tt}, \psi)_K + ((\eta_u)_{tt}, \psi)_K + (a \zeta_q, \nabla \psi)_K - (a^+ \zeta_q^+ \cdot \mathbf{v}, \psi)_{\partial K} = 0, \quad (3.16)
\]

\[
(\zeta_q, \phi)_K + (\eta_q, \phi)_K + (a \zeta_u, \nabla \cdot \phi)_K - (\zeta_u^-, a \phi \cdot \mathbf{v})_{\partial K} + (a \eta_u, \nabla \cdot \phi)_K - (\eta_u^-, a \phi \cdot \mathbf{v})_{\partial K} = -(\zeta_u \nabla a, \phi)_K - (\eta_u \nabla a, \phi)_K, \quad (3.17)
\]

Along the same line in the proof of Proposition 2.1, we first take the time derivative of Eq. (3.17), choose the test functions to be $\phi = \zeta_q$, $\psi = (\zeta_u)_t$, and then sum up the resulting two equations to get

\[
((\zeta_u)_{tt}, (\zeta_u)_t)_K + ((\eta_u)_{tt}, (\zeta_u)_t)_K + ((\zeta_q)_t, (\zeta_q)_t)_K + ((\eta_q)_t, (\zeta_q)_t)_K =
\]

\[
-(a \zeta_q, \nabla (\zeta_u)_t)_K + (a^+ \zeta_q^+ \cdot \mathbf{v}, (\zeta_u)_t)_{\partial K} - (a (\zeta_u)_t, \nabla \cdot (\zeta_q)_t)_K + ((\zeta_u)_t^-, a \zeta_q \cdot \mathbf{v})_{\partial K}
\]

\[
-(a (\eta_u)_t, \nabla \cdot (\zeta_q)_t)_K + ((\eta_u)_t^-, a \zeta_q \cdot \mathbf{v})_{\partial K} - ((\zeta_u)_t \nabla a, (\zeta_q)_t)_K - ((\eta_u)_t \nabla a, (\zeta_q)_t)_K.
\]

If the Dirichlet boundary conditions are imposed, the flux terms of the boundary cells $\mathcal{E}_h^B$ in the above equations will vanish, and therefore for simplicity, we only keep the notation for the internal cells.

Summing up the above equation over all cells and using integration by parts yields

\[
((\zeta_u)_{tt}, (\zeta_u)_t)_{\mathcal{T}_h} + ((\eta_u)_{tt}, (\zeta_u)_t)_{\mathcal{T}_h} + ((\zeta_q)_t, (\zeta_q)_t)_{\mathcal{T}_h} + ((\eta_q)_t, (\zeta_q)_t)_{\mathcal{T}_h} =
\]

\[
-(a (\eta_u)_t, \nabla \cdot (\zeta_q)_t)_{\mathcal{T}_h} + ((\eta_u)_t^-, a \zeta_q \cdot \mathbf{v})_{\mathcal{E}_h} - ((\eta_u)_t \nabla a, (\zeta_q)_t)_{\mathcal{T}_h}
\]

if periodic or Dirichlet boundary conditions are employed.
By the properties of the projections (3.3) and (3.8), one has

\[
\frac{1}{2} \frac{d}{dt} (\| \zeta_u \|^2 + \| \zeta_q \|^2) = \frac{1}{2} \frac{d}{dt} \int_I (\zeta_u^2 + \zeta_q^2) \, dx \\
\leq |((\eta_u)_t, (\zeta_u)_t)_{\Omega} + ((\eta_q)_t, \zeta_q)_{\Omega}| + C h^{k+1}\|u_t\|_{H^{k+2}(\Omega)} \| \zeta_q \| + |\nabla a|_{\infty} |(\eta_u)_t| \| \zeta_q \|
\leq C h^{k+1} (\| \zeta_u \| + \| \zeta_q \|) \leq C h^{k+1} (\| \zeta_u \|^2 + \| \zeta_q \|^2)^{\frac{1}{2}},
\]

which leads to

\[
\frac{d}{dt} (\| \zeta_u \|^2 + \| \zeta_q \|^2)^{\frac{1}{2}} \leq C h^{k+1}.
\]

Combining this inequality with the property of the initial condition (3.11), we conclude that

\[
(\| \zeta_u \|^2 + \| \zeta_q \|^2)^{\frac{1}{2}} \leq C (t+1) h^{k+1},
\]

in which the constant $C$ only depends on $|\nabla a|_{\infty}$, $\|u\|_{H^{k+3}}$ and $\|u_t\|_{H^{k+2}}$. Together with the optimal projection error (3.8), the error estimate (3.13) follows. \qed

3.3 Error estimate in the $L^2$ norm

In this section, we prove the optimal error estimate in the $L^2$ norm.

**Proposition 3.2.** Let $u$ and $q$ be the exact solutions of the wave equation (2.5), and $u_h$, $q_h$ be the numerical solutions of the semi-discrete LDG method (2.19)-(2.20) with the initial conditions (3.10), there holds the following error estimates:

\[
\max_{t \in [0,T]} \| e_u(t) \| \leq C h^{k+1}(T+1),
\]

where the constant $C$ only depends on the solution $u$ and $a$.

**Proof.** First, the term $(e_u)_{tt}$ is split as the summation of $(\zeta_u)_{tt}$ and $(\eta_u)_{tt}$ in Eq. (3.16), and by using chain rule in time derivative, one obtains

\[
-(\zeta_u, \psi_t)_K + (a \zeta_q, \nabla \psi)_K - (a^+ \zeta^+_q \cdot \nu, \psi)_{\partial K} = -(\eta_u, \psi)_K - \frac{d}{dt} ((\zeta_u, \psi)_K. \tag{3.19}
\]
For any time $\tau \leq T$, we denote the time integral of the error by

$$E_u(t) = \int_t^\tau e_u(s)ds, \quad E_u^\tau(t) = \int_t^\tau \eta_u(s)ds, \quad E_u^\tau(\tau) = \int_t^\tau \zeta_u(s)ds,$$

$$E_q(t) = \int_t^\tau e_q(s)ds, \quad E_q^\tau(t) = \int_t^\tau \eta_q(s)ds, \quad E_q^\tau(\tau) = \int_t^\tau \zeta_q(s)ds.$$

Integrating Eq. (3.15) in time, from $t$ to $\tau$ yields

$$(E_q, \phi)_K + (a E_u, \nabla \cdot \phi)_K - (E_u^- a \phi \cdot \nu)_{\partial K} = -(E_u \nabla a, \phi)_K. \quad (3.20)$$

If we choose the test functions to be $\psi = E_u^\tau(t)$ and $\phi = \zeta_q(t)$ in (3.19)-(3.20), and use the fact that $\psi_t = -\zeta_u(t)$, we have

$$((\zeta_u)_t, \zeta_u)_K + (a \zeta_q, \nabla E_u^\tau)_K - (a^\tau \zeta_q \cdot \nu, E_u^\tau)_{\partial K} = -((\eta_u)_t, E_u^\tau)_K - \frac{d}{dt}((\zeta_u)_t, E_u^\tau)_K;$$

$$ (E_q^\tau, \zeta_q)_K + (a E_u^\tau, \nabla \cdot \zeta_q)_K - ((E_u^\tau)^-, a \zeta_q \cdot \nu)_{\partial K} + (E_u^\tau \nabla a, \zeta_q)_K$$

$$= -(E_q^\tau, \zeta_q)_K - (a E_u^\tau, \nabla \cdot \zeta_q)_K + ((E_u^\tau)^-, a \zeta_q \cdot \nu)_{\partial K} - (E_u^\tau \nabla a, \zeta_q)_K.$$  

If the Dirichlet boundary conditions are used, the flux terms of the boundary cells $E_n^B$ in the above equations will vanish, and therefore for simplicity, we only keep the notation for the internal cells.

Adding up these two equations and summing over all cells, and using the periodic or Dirichlet boundary conditions, one obtains

$$\frac{1}{2} \frac{d}{dt} \left( \|\zeta_u\|^2 - \|E_q^\tau\|^2 \right) = -((\eta_u)_t, E_u^\tau)_{\tau_h} - \frac{d}{dt}((\zeta_u)_t, E_u^\tau)_{\tau_h} - (E_q^\tau, \zeta_q)_{\tau_h}$$

$$- (a E_u^\tau, \nabla \cdot \zeta_q)_{\tau_h} + ((E_u^\tau)^-, a \zeta_q \cdot \nu)_{\varepsilon_h} - (E_u^\tau \nabla a, \zeta_q)_{\tau_h}.$$  

Integrating the above equation from 0 to $\tau$, we get

$$\frac{1}{2} \left| \zeta_u(\tau) \right|^2 - \frac{1}{2} \left| \zeta_u(0) \right|^2 + \frac{1}{2} \left| E_q^\tau(0) \right|^2$$

$$= - \int_0^\tau (\eta_u)_t, \zeta_u)_{\tau_h} dt + ((e_u)_t(0), E_u^\tau(0))_{\tau_h} - \int_0^\tau (E_q^\tau, \zeta_q)_{\tau_h} dt$$

$$+ \int_0^\tau (-a E_u^\tau, \nabla \cdot \zeta_q)_{\tau_h} + ((E_u^\tau)^-, a \zeta_q \cdot \nu)_{\varepsilon_h} - (E_u^\tau \nabla a, \zeta_q)_{\tau_h}) dt. \quad (3.21)$$
in which we use the fact \(E_q^\tau(\tau) = E_q^\tau(\tau) = 0\). By the property of the projection (3.8), we have \(\|E_u^0_t\| = Ch^{k+1}\). Note that

\[
E_q^0(t) = \int_t^\tau \eta_q(s)ds = \int_t^\tau (q(s) - P^- q(s)) ds = \int_t^\tau q(s)ds - P^- \left( \int_t^\tau q(s)ds \right),
\]

and therefore we can conclude that \(\|E_q^0\| = Ch^{k+1}\). Due to the property of projection \(P^- (3.3)\), one has

\[
-(aE_u^0, \nabla \cdot \zeta_q)_{\mathcal{T}_h} + ((E_u^0)^-, a\zeta_q \cdot \nu)_{\mathcal{E}_h} - (E_u^0 \nabla a, \zeta_q)_{\mathcal{T}_h}
\leq Ch^{k+1}\|\zeta_q\|_\Omega + |\nabla a|_\infty \|E_q^0\|_\Omega \|\zeta_q\|_\Omega \leq Ch^{2k+2}(T + 1),
\]

where the last inequality comes from the error estimate (3.13) of \(q\). Combining with the property of the \(L^2\) projection (3.12), we have

\[
\frac{1}{2}\|\zeta_u(\tau)\|^2 - \frac{1}{2}\|\zeta_u(0)\|^2 + \frac{1}{2}\|E_q^\tau(0)\|^2 \\
\leq \left| \int_0^\tau ((\eta_u)_t, \zeta_u)_{\mathcal{T}_h} dt \right| + \left| \int_0^\tau (E_q^\tau, \zeta_u)_{\mathcal{T}_h} dt \right| + Ch^{2k+2}(T + 1)\tau
\leq \int_0^\tau \|\eta_u\|_t \|\zeta_u\| dt + \int_0^\tau \|E_q^\tau\| \|\zeta_u\| dt + Ch^{2k+2}(T + 1)\tau
\leq \tau \max_{t \in [0,\tau]} \|\eta_u\| \max_{t \in [0,\tau]} \|\zeta_u\| + \tau \max_{t \in [0,\tau]} \|E_q^\tau\| \max_{t \in [0,\tau]} \|\zeta_u\| + Ch^{2k+2}(T + 1)\tau
\leq T \left( \max_{t \in [0,T]} \|\eta_u\| \max_{t \in [0,T]} \|\zeta_u\| + \max_{t \in [0,T]} \|E_q^\tau\| \max_{t \in [0,T]} \|\zeta_u\| + Ch^{2k+2}(T + 1) \right)
\leq CT \left( h^{k+1} \max_{t \in [0,T]} \|\zeta_u\| + (T + 1)h^{2k+2} \right)
\leq C(T^2 + 1)h^{2k+2} + \frac{1}{4} \max_{t \in [0,T]} \|\zeta_u\|^2.
\]

Since this is true for any \(\tau < T\), we have

\[
\frac{1}{2}\|\zeta_u(\tau)\|^2 - \frac{1}{2}\|\zeta_u(0)\|^2 + \frac{1}{2}\|E_q^\tau(0)\|^2 \leq C(T^2 + 1)h^{2k+2} + \frac{1}{4} \max_{t \in [0,T]} \|\zeta_u\|^2.
\]

Hence,

\[
\frac{1}{4} \max_{t \in [0,T]} \|\zeta_u\|^2 + \frac{1}{2}\|E_q^\tau(0)\|^2 \leq C(T^2 + 1)h^{2k+2} + \frac{1}{2}\|\zeta_u(0)\|^2 = C(T^2 + 1)h^{2k+2},
\]

from which we can conclude

\[
\max_{t \in [0,T]} \|e_u(t)\| \leq Ch^{k+1}(T + 1).
\]
where the constant $C$ only depends on the solution $u$ and $a$.

**Remark 3.2.** The proposed semi-discrete LDG method has the advantage of energy conserving and optimal convergence rate. The proof of optimal error estimate is carried out with the $Q^k$ polynomial space. Numerically, we can observe the same results if $P^k$ space is used, as shown in Section 5. However it seems to be difficult to prove this fact, as the special projection introduced in the subsection 3.1 does not exist in the $P^k$ space.

## 4 Time discretization

In this section, we develop fully discrete method that maintains the energy conservation property of the semi-discrete methods. To achieve this, it is essential to employ time stepping methods that conserve the discrete energy. In the following, we introduce a second order time stepping (leap frog), and a high order symplectic time integrator.

In general, one obtains the semi-discrete scheme (2.19)-(2.20) after the spatial discretization by the LDG method. Note that we can solve $q_h$ in terms of $u_h$ in (2.20) in an element-by-element fashion. This local solvability gives the name to the LDG method, and we refer to [14] for details. Eliminating the auxiliary variable $q_h$ leads to the linear second-order ordinary differential system:

$$M \ddot{u}_h(t) = A u_h(t),$$  \hspace{1cm} (4.1)

where $u_h(t)$ denotes the solution vector at time $t$ and $M$ denotes the mass matrix.

### 4.1 Second order time stepping

Newmark method is a family of single-step integration methods, proposed by Newmark [29] in 1959, for the solution of structural dynamics problems. It has been applied to dynamics analysis of many practical engineering problems during the last forty years. In [26], Newmark method is shown to belong to the category of variational algorithms, which are well known to be symplectic and momentum preserving and to often have excellent global energy behaviour.
A special case in the Newmark family is the standard leap-frog method, which is well-known to be energy conserving.

Let $0 \leq t_0 < t_1 < \cdots < t_N = T$ be a partition of the interval $[0, T]$ with time step $\Delta t_n = t_{n+1} - t_n$. Here uniform time step $\Delta t$ is used. The fully discrete approximations $u^n_h$ to $u(\cdot, t_n)$ are constructed as follows: for $n = 1, \ldots, N - 1$, $u^{n+1}_h \in V_h^k$ is given by

$$M \frac{u^{n+1}_h - 2u^n_h + u^{n-1}_h}{\Delta t^2} = Au^n_h,$$

based on the system (4.1), and more precisely,

\[
\begin{align*}
\left( \frac{u^{n+1}_h - 2u^n_h + u^{n-1}_h}{\Delta t^2}, \psi \right)_K + (aq^n_h, \nabla \psi)_K - (a^+(q^n)_h^+ \cdot \nu, \psi)_\partial K &= 0, \\
(q^n_h, \phi)_K + (au^n_h, \nabla \cdot \phi)_K - ((u^n)^-, a\phi \cdot \nu)_\partial K &= -(u^n\nabla a, \phi)_K,
\end{align*}
\]

for all test functions $\psi \in V_h^k$ and $\phi \in \Sigma_h^k$.

In Proposition 2.1, we have shown the semi-discrete LDG method conserves the continuous energy $E_h(t)$. Along the same line of analysis, we can prove that the discrete energy, as defined in the following proposition, is conserved in the fully discrete method.

**Proposition 4.1.** The solution to the fully discrete leap-frog LDG method (4.3)-(4.4), conserves the (discrete) energy

$$E^{n+1}_h = \left\| \frac{u^{n+1}_h - u^n_h}{\Delta t} \right\|^2 + \left\| \frac{q^{n+1}_h + q^n_h}{2} \right\|^2 - \frac{\Delta t^2}{4} \left\| \frac{q^{n+1}_h - q^n_h}{\Delta t} \right\|^2$$

for all $n$.

**Proof.** We choose the test function in (4.3) to be $\psi = (u^{n+1}_h - u^n_h)/(2\Delta t) + (u^n_h - u^{n-1}_h)/(2\Delta t) = (u^{n+1}_h - u^{n-1}_h)/(2\Delta t)$, and obtain

\[
\begin{align*}
\left( \frac{u^{n+1}_h - 2u^n_h + u^{n-1}_h}{\Delta t^2}, \frac{u^{n+1}_h - u^{n-1}_h}{2\Delta t} \right)_K + \left( aq^n_h, \nabla \left( \frac{u^{n+1}_h - u^{n-1}_h}{2\Delta t} \right)_K \right)_K \\
- \left( a^+(q^n)_h^+ \cdot \nu, \frac{u^{n+1}_h - u^{n-1}_h}{2\Delta t} \right)_\partial K &= 0.
\end{align*}
\]
Consider Eq. (4.4) at time levels $t^{n-1}$ and $t^{n+1}$, and let the test function $\phi$ be $q_h^n/(2\Delta t)$. Subtracting these two equations yields

\[
\left( \frac{q_h^{n+1} - q_h^{n-1}}{2\Delta t}, q_h^n \right)_K + \left( \frac{u_h^{n+1} - u_h^{n-1}}{2\Delta t}, \nabla \cdot q_h^n \right)_K - \left( \frac{(u_h^{n+1})^2 - (u_h^{n-1})^2}{2\Delta t}, aq_h^n \cdot \nu \right)_{\partial K} = - \left( \frac{u_h^{n+1} - u_h^{n-1}}{2\Delta t} \nabla a, q_h^n \right)_K .
\] (4.7)

Adding Eqs. (4.6) to (4.7) and summing over all cells gives

\[
\frac{1}{2\Delta t} \left( \left\| \frac{u_h^{n+1} - u_h^n}{\Delta t} \right\|^2 + \left\| \frac{q_h^{n+1} - q_h^n}{2\Delta t} \right\|^2 - \Delta t^2 \left\| \frac{q_h^{n+1} - q_h^n}{\Delta t} \right\|^2 \right) - \left\| \frac{u_h^n - u_h^{n-1}}{\Delta t} \right\|^2 - \left\| \frac{q_h^n - q_h^{n-1}}{2\Delta t} \right\|^2 + \frac{\Delta t^2}{4} \left\| \frac{q_h^{n+1} - q_h^n}{\Delta t} \right\|^2 = 0 .
\]

Therefore, by the definition of $E_h^n$ in (4.5), we have $E_h^{n+1} = E_h^n$ for all $n$, which completes the proof. \[\square\]

**Remark 4.1.** The discrete energy $E_h^n$ can be rewritten as:

\[
E_h^{n+1} = \int_{\Omega} \left( \frac{u_h^{n+1} - u_h^n}{\Delta t} \right)^2 \, dx + \int_{\Omega} \frac{q_h^{n+1} - q_h^n}{\Delta t} \, dx ,
\] (4.8)

which is a consistent approximation of the continuous energy (2.21).

### 4.2 High order time stepping

The spatial discretization of the proposed method is by local discontinuous Galerkin method, which can be high order accurate depending on the polynomial degree $k$ utilized in the space $V_h^k$. Therefore, we would like to present high order time stepping which also conserves the energy exactly. Such numerical methods have been designed from the modified equation
approach [32, 17, 33]. Following the same technique, we will present an energy-conserving fourth-order time discretization below. This idea can be extended to derive higher order methods.

For a smooth function \(u\), simple calculus leads to

\[
    u(t + \Delta t) - 2u(t) + u(t - \Delta t) = \Delta t^2 \int_{-1}^{1} (1 - |\theta|) u''(t + \theta \Delta t) d\theta. \quad (4.9)
\]

Therefore, the leap-frog method is obtained by simply approximating \(u''(t + \theta \Delta t)\) with \(u''(t)\) on the right hand side, i.e.

\[
    u(t + \Delta t) - 2u(t) + u(t - \Delta t) = \Delta t^2 u''(t).
\]

Extension to high order version can be derived by the modified equation approach, as shown in [17, 32]. To obtain a fourth-order time discretization, we consider the Taylor expansion of \(u''(t + \theta \Delta t)\) and the first three terms are:

\[
    u''(t + \theta \Delta t) \approx u''(t) + \theta \Delta t u''(t) + \theta^2 \Delta t^2 u^{(4)}(t).
\]

Inserting the above approximation into Eq. (4.9), the integral of odd powers of \(\theta\) vanishes, and we have

\[
    u(t + \Delta t) - 2u(t) + u(t - \Delta t) = \Delta t^2 \left( u''(t) + \frac{\theta^2 \Delta t^2}{12} u^{(4)}(t) \right). \quad (4.10)
\]

We comment here that if one considers a time integrator more accurate than fourth order, more terms should be included in the Taylor expansion. Applying (4.10) to the differential system (4.1), and utilizing the fact that \(u^{(4)}(t) = M^{-1} A \ddot{u}_h(t) = (M^{-1} A)^2 \dot{u}_h(t)\), one has the fourth-order method:

\[
    \frac{u^{n+1}_h - 2u^n_h + u^{n-1}_h}{\Delta t^2} = M^{-1} A u^n_h + \frac{\Delta t^2}{12} (M^{-1} A)^2 u^n_h. \quad (4.11)
\]

It has been shown that the largest time step of this fourth-order method is \(\sqrt{3}\) of that of the leap-frog method [16, 33], and therefore the computational cost is comparable yet the
accuracy is improved. In our numerical simulations, we use Eq. (4.11) as the fourth-order time integrator.

We remark here that the same fourth-order method has been reformulated into a predictor-corrector method in [33]: for \( n = 1, \ldots, N - 1 \), \( u_h^{n+1} \in V^k_h \) is given by

\[
M u_h^* - 2u_h^n + u_h^{n-1} = A u_h^n, \tag{4.12}
\]

\[
M u_h^{n+1} = M u_h^* + \frac{\Delta t^4}{12} A v_h, \quad v_h = \frac{u_h^* - 2u_h^n + u_h^{n-1}}{\Delta t^2}, \tag{4.13}
\]

based on the system (4.1). More precisely, it can be rewritten in the form of a second-order predictor step

\[
\left( \frac{u_h^* - 2u_h^n + u_h^{n-1}}{\Delta t^2}, \psi \right)_K + (a q_h^n, \nabla \psi)_K - (a^+(q^n)_h^+ \cdot \nu, \psi)_{\partial K} = 0, \tag{4.14}
\]

\[
(q_h^n, \phi)_K + (a u_h^n, \nabla \cdot \phi)_K - ((u_h^n)^-, a \phi \cdot \nu)_{\partial K} = -(u_h^n \nabla a, \phi)_K, \tag{4.15}
\]

and the corrector step

\[
v_h = \frac{u_h^* - 2u_h^n + u_h^{n-1}}{\Delta t^2}, \tag{4.16}
\]

\[
(w_h, \phi)_K + (a v_h, \nabla \cdot \phi)_K - ((v_h)^-, a \phi \cdot \nu)_{\partial K} = -(v_h \nabla a, \phi)_K, \tag{4.17}
\]

\[
(u_h^{n+1}, \psi)_K = (u^*, \psi)_K + \frac{\Delta t^4}{12} (a w_h, \nabla \psi)_K - \frac{\Delta t^4}{12} (a^+(w)_h^+ \cdot \nu, \psi)_{\partial K} = 0, \tag{4.18}
\]

for all test functions \( \psi \in V^k_h \) and \( \phi \in \Sigma^k_h \).

5 Numerical experiments

5.1 Example 1: Wave equation with a constant coefficient

5.1.1 Accuracy test in \( Q^k \) space

We consider the 2D wave equation with a constant coefficient, which is taken to be 1,

\[
u_{tt} = \nabla^2 u, \quad (x, y) \in [0, 2] \times [0, 2], \tag{5.1}
\]

with initial condition

\[
u(x, y, 0) = \cos(\pi x) \cos(\pi y), \quad \nu_t(x, y, 0) = 0,

and periodic boundary conditions $u(0, y, t) = u(2, y, t)$ and $u(x, 0, t) = u(x, 2, t)$, for all $0 \leq x \leq 2, 0 \leq y \leq 2$ and $t \geq 0$.

This problem has the exact solution

$$u(x, y, t) = \cos(\sqrt{2}\pi t) \cos(\pi x) \cos(\pi y).$$

We implemented the LDG method with the alternating fluxes (2.9) and use the time integrator (4.11) with time step $\Delta t = 0.2/(\Delta x^2 + \Delta y^2)$. Since the symplectic time integrator requires initial conditions for two time steps, we consider Taylor expansion of $u$ at $t = 0$:

$$u(x, y, \Delta t) = u(x, y, 0) + \Delta t u_t(x, y, 0) + \frac{\Delta t^2}{2} u_{tt}(x, y, 0) + \frac{\Delta t^3}{6} u_{ttt}(x, y, 0) + O(\Delta t^4),$$

and convert the higher derivatives of $t$ to derivatives of $x$ and $y$ by repeatedly using the wave equation, while $u$ and $u_t$ are given by initial conditions. To obtain the desired order of convergence of $u$, following the initial conditions (3.10), we take the projection $P^{+}_h$ of $u(x, y, 0)$, and $L^2$ projection $P_h$ of $u_t(x, y, 0)$. In other words, with $u(x, y, 0)$ denoted by $u_0$ and $u_t(x, y, 0)$ by $v_0$, we use the initial conditions:

$$u^0_h = P^{-}_h u_0,$$
$$u^1_h = u^0_h + \Delta t P_h v_0 + \frac{\Delta t^2}{2} P^{-}_h \{ (\partial_{xx} + \partial_{yy})u_0 \} + \frac{\Delta t^3}{6} P_h \{ (\partial_{xx} + \partial_{yy})v_0 \}. \quad (5.3)$$

Tables 5.1 - 5.3 list the numerical errors and the orders of convergence for $Q^k$ spaces, $k = 1, 2, 3$. In each table, the $L^2$-norm of the errors $e_u$, $e_p$, and $e_q$ at the final time $T = 1$ are presented. The $(k + 1)$th order for all the errors of $u, p, q$ can clearly be observed.

5.1.2 Accuracy test in $Q^k$ space with standard $L^2$ projections for initial conditions

To show that the special projections of the initial condition $u_0$ in (5.2) is indeed critical for optimal rate of convergence, we test the problem with the same setting, but with standard $L^2$ projections for both $u_0$ and $v_0$. Tables 5.4 - 5.5 list the numerical errors and the orders of convergence for $Q^1$ and $Q^2$ spaces. We can observe that the order of accuracy for $u$, $u_x$, and $u_y$ is oscillating. When $Q^2$ space is used, the accuracy of $u_x$ and $u_y$ is close to 2, which means only suboptimal convergence rate is obtained. This oscillating behavior of numerical accuracy is commonly observed for energy conserving methods, and a least square fitting of the order [34] may give the optimal convergence rate of $u$. We notice that in subsection 5.1.1, different initial conditions are employed and optimal convergence rate is clearly observed there. Previous studies on LDG methods showed that the different choices of initial condition have little impact on the convergence/superconvergence results [7, 27, 24]. This test demonstrates that our energy conserving method is more sensitive to the error in the initial conditions, probably due to the fact that no numerical dissipation is included in these methods to dissipate the initial error.

5.1.3 Accuracy test in $P^k$ space

We consider the same problem and setup, but replace the DG spaces by $P^k$, which is the polynomial space that has degree at most $k$, namely, $\{\sum_{i,j} x^i y^j : i, j \in \mathbb{N}, i + j \leq k\}$. According to extensive numerical experiments in previous works, $(k+1)$-th order accuracy can usually be observed for the $P^k$ space. Since the space $P^k$ is smaller than $Q^k$, using $P^k$ will be more efficient in order to obtain $(k+1)$-th order accuracy. However, theoretically it is very difficult to prove the optimal order of accuracy for $P^k$ space, and therefore in this paper, we only perform numerical experiments. As for the initial conditions, we simply project the initial conditions (5.2)-(5.3), which is defined in $Q^k$, to space $P^k$.

The order of accuracy with spaces $P^1$, $P^2$ and $P^3$ are shown in Tables 5.6-5.8. For $P^1$, second order accuracy can be observed in all the variables $u$, $p$ and $q$. However, for $P^2$ and $P^3$, $(k+1)$-th order can be achieved in $u$, but only $k$-th order of accuracy is seen in $p$ and $q$. This loss of accuracy in $p$ and $q$ may be resulted from the initial projection (5.2)-(5.3), which

has been shown essential for the $Q^k$ space, but appears not to produce the same optimal order of accuracy for the $P^k$ space.

5.1.4 Accuracy test with central flux in the $Q^k$ space

While claiming that the advantage of using alternating flux as proposed in this paper is to conserve energy, it is arguable that in (2.6), (2.13) and (2.14) using the central flux

$\tilde{aq}_h^1 = \{\{aq_h\}\}, \quad \tilde{u}_h = \{\{u_h\}\},$

and

$\tilde{aq}_h^2 = \{\{aq_h\}\}, \quad \tilde{u}_h = \{\{u_h\}\},$

where $\{\{u\}\} = \frac{u^- + u^+}{2}$, may also conserve energy, as is known when applied for first order hyperbolic equations. However, a well-known disadvantage of central flux is its order of accuracy oscillates, depending on if $k$ is even or odd. Here we implement the LDG scheme, with central flux and show that the order of accuracy indeed oscillates (Table 5.9): the order for even $k$ is $k + 1$ and the order for odd $k$ is $k$. Therefore it is not an optimal energy preserving method to use for any desired order of accuracy.

5.1.5 Time history of the $L^2$ error

To demonstrate that our proposed method is energy conserving, as proved in Section 2 and 4, we simulate the problem in Example 1 until $T = 100$, and monitor the $L^2$ error of the numerical solution. It can be seen in Fig. 5.1 that the $L^2$ error stays at the level of $10^{-5}$ for $Q^2$ and $10^{-7}$ for $Q^3$, and the average values do not grow in time. We also simulated with the central flux for $Q^2$ and $Q^3$. Since the central flux also preserves energy, the $L^2$ error also remains constant in average. However, due to the nature of the oscillating order of accuracy, the $L^2$ error for $Q^2$ is comparable to that of alternating flux, but the error for $Q^3$ is much higher than using alternating flux.

5.2 Example 2: Wave equation with discontinuous coefficient

We consider the 2D wave equation

$$u_{tt} = \nabla \cdot (c(x, y)\nabla u),$$
Figure 5.1: Example 1 with $Q^k$ space. Time history until $T = 100$ of the $L^2$ error of the numerical approximations obtained from using the alternating flux (red) and central flux (blue), with $k = 2, 3$. A uniform $40 \times 40$ grid is used. The $L^2$ error of $u$ on $y$-axis are presented in log scale.

Table 5.10: Example 2: numerical errors and orders with uniform meshes and space $Q^2$.

with a discontinuous coefficient in the domain $\Omega = \{(x, y) | (x, y) \in [-2, 2] \times [0, 1]\}$. The domain $\Omega$ is composed of two subdomains $\Omega_1 = [-1, 1] \times [0, 1]$ and $\Omega_2 = \Omega \setminus \Omega_1$, and if the coefficient $c(x, y)$ is defined as

$$a(x, y) = \begin{cases} 
\frac{9}{34}, & \text{in } \Omega_1 \\
\frac{1}{2}, & \text{in } \Omega_2 
\end{cases}$$

and periodic boundary conditions are imposed, then the solution is

$$u(x, y, t) = \begin{cases} 
\cos (3\pi t) \cos (5\pi x) \cos (3\pi y), & \text{in } \Omega_1 \\
\cos (3\pi t) \cos (3\pi x) \cos (3\pi y), & \text{in } \Omega_2.
\end{cases}$$

By using the alternating flux (2.15)-(2.16) designed for this type of problem, we test the order of accuracy for $Q^k$ (k=1,2,3) and present the results of $Q^2$ space in Table 5.10. Third order accuracy can be clearly seen in all the variables.
5.3 Example 3: Isotropic wave propagation within heterogeneous media

We consider the 2D wave equation Eq. (2.1) with discontinuous coefficient in the domain $[0, 1] \times [0, 1]$, with the coefficient $c(x, y)$ defined as

$$c(x, y) = \begin{cases} \frac{1}{4}, & \text{if } x \leq 0.65, \\ 1, & \text{if } x > 0.65. \end{cases}$$

The initial condition is given by

$$u_0(x, y) = 0 \quad \text{and} \quad u_0(x, y) = 2e^{-500((x-0.5)^2+(y-0.5)^2)}.$$

and zero boundary conditions are imposed for all the boundaries. Fig. 5.2 shows the time evolution of the wave propagation: initially the wave propagates isotropically, until it reaches the interface of two media (around $T = 0.25$ to 0.3), and at a later time, the wave fronts propagate at different speeds in these two media. To verify the convergence of our numerical solutions, we compared snapshots of the 2D contour at $T = 0.5$ with $40 \times 40$ and $80 \times 80$ cells, and the contours agree very well (Fig. 5.3). We further compared, for these two meshes, the cross sections at $y = 0.4$ for $T = 0.05, 0.3, 0.5$. In Fig. 5.4, it can be seen that the one-dimensional profiles matches very well.

6 Concluding remarks

In this paper, we have developed an LDG method for multi-dimensional wave problems in discontinuous media. As is well known, energy conservation is one of the most important properties of wave equations, and therefore this is the aimed property of our numerical method aside high order convergence rate. To obtain such a scheme, we carefully designed numerical fluxes and projections of the initial conditions. We also developed compatible time integrators, such as a second-order (leap-frog) and a fourth-order energy preserving method. We proved the optimal error estimate for the semi-discrete method, and also showed that our scheme preserves energy in the discrete sense. Numerous numerical examples were shown to demonstrate the optimal convergence rate and energy conservation property.
Figure 5.2: Example 3: Two-dimensional contours of the numerical approximations at time $T = 0.05, 0.25, 0.3, 0.4, 0.45, 0.5$. The DG space used is $Q^2$ and the grid is uniform with $40 \times 40$ cells.

Figure 5.3: Example 3: Comparison of the 2D contours using $40 \times 40$ cells (left) and $80 \times 80$ cells (right), at $T = 0.5$. 
Future works include the generalization of the LDG scheme to wave equations, of which the discontinuities of the coefficients are not aligned with the Cartesian grid. Schemes on unstructured triangular meshes will also be developed to accommodate general computational domains.
